We study the thermodynamics near the generic (density-driven) superfluid–Mott-insulator transition in the three-dimensional Bose-Hubbard model using the nonperturbative renormalization-group approach. At low energy, the physics is controlled by the Gaussian fixed point and becomes universal. Thermodynamic quantities can then be expressed in terms of the universal scaling functions of the dilute Bose gas universality class while the microscopic physics enters only via two nonuniversal parameters, namely, the effective mass $m^*$ and the “scattering length” $a^*$ of the elementary excitations at the quantum critical point between the superfluid and Mott-insulating phases. A notable exception is the condensate density in the superfluid phase which is proportional to the quasiparticle weight $Z_{qp}$ of the elementary excitations. The universal regime is defined by $m^* a^* T \ll 1$ and $m^* a^* |\delta \mu | \ll 1$ or, equivalently, $|\bar{n} - \bar{n}_c| a^3 \ll 1$, where $\delta \mu = \mu - \mu_c$, is the chemical potential shift from the quantum critical point ($\mu = \mu_c$, $T = 0$) and $\bar{n} - \bar{n}_c$ the doping with respect to the commensurate density $\bar{n}_c$ of the $T = 0$ Mott insulator. We compute $Z_{qp}$, $m^*$, and $a^*$ and find that they vary strongly with both the ratio $t/U$ between hopping amplitude and onsite repulsion and the value of the (commensurate) density $\bar{n}_c$. Finally, we discuss the experimental observation of universality and the measurement of $Z_{qp}$, $m^*$, and $a^*$ in a cold-atomic gas in an optical lattice.

I. INTRODUCTION

The low-temperature thermodynamics of a dilute ultracold Bose gas is well understood both theoretically and experimentally. The equation of state, e.g., the pressure $P(\mu, T)$ versus chemical potential and temperature, turns out to be “universal” to the extent that it depends only on a small number of parameters such as the mass $m$ of the bosons and their $s$-wave scattering length $a$, and is otherwise independent of other microscopic characteristics such as details of the atom-atom interaction potential. From a theoretical point of view, the thermodynamics of a dilute Bose gas is usually derived within a low-density expansion using $ma^2 \mu$ (or $\bar{n} a^3$, with $\bar{n}$ the mean boson density) as the expansion parameter.

Strong correlations in an ultracold Bose gas can be achieved by loading the gas into an optical lattice. It is then possible to induce a quantum phase transition between a superfluid ground state and a Mott-insulating phase by varying the strength of the lattice potential [1]. The main features of the Mott transition can be understood in the framework of the Bose-Hubbard model, which describes bosons moving in a lattice with an onsite repulsive interaction [2].

In the vicinity of the Mott transition, there is no small parameter (such as density or interaction strength) that would allow us to derive the equation of state perturbatively. Nevertheless, near the generic (density-driven) Mott transition, the thermodynamics of a Bose gas turns out to be similar to that of a dilute Bose gas up to some effective parameters. The origin of this similarity can be understood as follows. By varying the chemical potential from negative to positive values in a dilute Bose gas, one induces a (zero-temperature) quantum phase transition between a state with no particles (vacuum) and a superfluid state with a finite density. This identifies the point $\mu = T = 0$ as a quantum critical point (QCP). Above the upper critical dimension $d^* = 2$, the boson-boson interaction is irrelevant (in the renormalization-group sense) and the critical behavior at the transition is mean-field like with a correlation-length exponent $\nu = 1/2$ and a dynamical critical exponent $z = 2$. Elementary excitations at the QCP are free bosons of mass $m$ and their mutual interaction is determined by the $s$-wave scattering length $a$ in the low-energy limit. The dependence of the equation of state of a dilute Bose gas on $m$ and $a$ only is a direct consequence of the proximity of the QCP between the superfluid phase and the vacuum: the thermodynamics is controlled by the QCP. It follows that thermodynamic quantities can be expressed in terms of universal scaling functions of $\mu/T$ and an effective temperature-dependent dimensionless interaction constant $\tilde{g}(T) = 8\pi \sqrt{2ma^2 T}$ [3]. This universal description holds in the critical regime of the QCP defined by $ma^2 |\delta \mu |$ and $ma^2 T \ll 1$.

The vacuum-superfluid transition of a dilute Bose gas and the generic Mott transition of a Bose gas in an optical lattice are described by the same low-energy effective theory [4]. They therefore belong to the same universality class and are governed by the same (Gaussian) fixed point. Elementary excitations at the QCP between the Mott insulator and the superfluid phase are quasiparticles with effective mass $m^*$ and their mutual interaction is described by an effective “scattering length” $a^*$. Near the QCP, thermodynamic quantities can be expressed with the universal scaling functions of the dilute Bose gas universality class and the nonuniversal parameters $m^*$ and $a^*$. This conclusion is correct everywhere near the superfluid–Mott-insulator transition except in the close vicinity of the multicritical points where the transition takes place at fixed (commensurate) density (Fig. 1).

In this paper, we study the thermodynamics of the three-dimensional Bose-Hubbard model using a nonperturbative renormalization-group (NPRG) approach [5–7]. In Sec. II, we derive scaling forms for various thermodynamic quantities (pressure, density, compressibility, condensate density, superfluid stiffness, and superfluid transition temperature) of a dilute...
Bose gas and discuss the scaling functions in some limiting cases. The nonperturbative renormalization-group approach to the Bose-Hubbard model is briefly reviewed in Sec. III. In Sec. IV, we show that the NPRG approach enables us to straightforwardly identify the elementary excitations at the QCP governing the generic Mott transition, and compute their effective mass $m^*$ and effective scattering length $a^*$ as well as their spectral weight $Z_{pp}$, $Z_{pp}$, $m^*$, and $a^*$ are calculated as a function of $t/U$. We then present various thermodynamic quantities obtained from a numerical solution of the NPRG equations and show that near the Mott transition, they satisfy the scaling behavior characteristic of the dilute Bose gas universality class, except for the condensate density which is proportional to the quasiparticle weight. The experimental implications of our results are discussed in Sec. V.

II. DILUTE BOSE GAS UNIVERSALITY CLASS

In this section, we discuss in detail the dilute Bose gas universality class. We derive scaling forms for various thermodynamic quantities and compute the corresponding universal scaling functions in some limits.

A. Universal scaling functions

Let us consider a three-dimensional Bose gas described by the (Euclidean) action

$$S = \int_0^\beta d\tau \int d^3r \left\{ \psi^* \left( \partial_\tau - \mu + \frac{\nabla^2}{2m} \right) \psi + \frac{g}{2} \psi^* \psi \right\},$$

(1)

where $\psi(\mathbf{r}, \tau)$ is a complex field and $\tau \in [0,\beta]$ an imaginary time with $\beta = 1/T$ the inverse temperature. $\mu$ denotes the chemical potential. The interaction is assumed to be local in space and the model is regularized by an ultraviolet momentum cutoff $\Lambda$. $d = 3$ and we set $\hbar = k_B = 1$ throughout the paper.

The nature of the $\mu = T = 0$ QCP between the vacuum and the superfluid state can be understood from a RG analysis. Since the $\mu = 0$ ground state is the vacuum, there is no renormalization of the single-particle propagator and the correlation-length exponent $n = 1/2$, the anomalous dimension $\eta = 0$ while the dynamical critical exponent $z = 2$. The dimensionless interaction constant $\bar{g} = 2mg\Lambda$ satisfies the (exact) RG equation

$$-\frac{dg(s)}{ds} = \bar{g}(s) - \frac{\bar{g}(s)^2}{4\pi^2}$$

(2)

with $\bar{g}(1) = \bar{g}$, when fluctuation modes with momenta between $\Lambda$ and $\Lambda/s$ are integrated out (with a proper rescaling of fields, momenta, and frequencies in order to restore the original value of the cutoff $\Lambda$) [3,4]. From Eq. (2), we obtain

$$\bar{g}(s) = \frac{8\pi\Lambda a}{s} \quad \text{for} \quad s \gg 1,$$

(3)

where

$$a = \frac{mg}{4\pi + \frac{2}{\pi}mg\Lambda},$$

(4)

is the $s$-wave scattering length which can be calculated from the action (1) by solving the two-body problem. $\bar{g}(s)$ is thus irrelevant (it vanishes for $s \to \infty$) and the only fixed point of Eq. (2) is $\bar{g} = 0$, in agreement with the fact that the upper critical dimension for the vacuum-superfluid transition is $d^+ = 2$.

There are two relevant perturbations about the Gaussian fixed point $\mu = T = \bar{g} = 0$: the chemical potential $\mu$ and the temperature $T$, with scaling dimensions $[\mu] = 1/v$ and $[T] = z$. In a RG transformation, they transform as $\mu(s) = s^{1/v}\mu$ and $T(s) = s^zT$. In the critical regime near the QCP, the pressure satisfies [8]

$$P(\mu, T) = s^{-d-z}P(s^{1/v}\mu, s^zT, \bar{g}(s)).$$

(5)

By choosing $s \sim T^{-1/2}$ or $s \sim |\mu|^{-\nu}$ and setting $z = 1/v = 2$ (with $d = 3$), we can write the pressure in the scaling form

$$P(\mu, T) = \left( \frac{m}{2\pi} \right)^{3/2} T^{5/2} |T|^{1/2} g(|\mu|^2, \bar{g}(T))$$

(6)

or

$$P(\mu, T) = \left( \frac{m}{2\pi} \right)^{3/2} \mu^{5/2} \bar{g}(\frac{T}{\mu}, \bar{g}(|\mu|^2)).$$

(7)

The overall factor $m^{3/2}$ comes from dimensional considerations, while the factor $1/(2\pi)^{3/2}$ is introduced for convenience [3]. The energy-dependent effective (dimensionless) interaction constant $\tilde{g}(\epsilon) \equiv \bar{g}(s = \Lambda/\sqrt{2m|\epsilon|})$ is defined by

$$\tilde{g}(\epsilon) = 8\pi \sqrt{2ma^2|\epsilon|}$$

(8)

and is entirely determined by the mass $m$ of the bosons and the scattering length $a$. $F$ and $G$ are universal scaling functions characteristic of the three-dimensional dilute Bose gas universality class. Equations (6) and (7) are valid in the critical regime near the QCP defined by $ma^2|\mu| \ll 1$ and $ma^2 T \ll 1$. Note that the interaction constant $\tilde{g}$ is a dangerously irrelevant variable (in the RG sense) and therefore
can not be neglected: \( F \) and \( G \) are singular functions of \( \tilde{g}(T) \) or \( \tilde{g}(\mu) \). Higher-order interactions, such as three-body interactions, are not considered here since they are irrelevant and give rise to subleading contributions to the pressure.

Equations (6) and (7) imply scaling forms for other thermodynamic quantities. For example, the particle density and compressibility read as

\[
\tilde{n}(\mu, T) = \frac{\partial P}{\partial \mu} = \left( \frac{m}{2\pi} \right)^{3/2} T^{1/2} F(0, 0) \left( \frac{\mu}{T}, \tilde{g}(T) \right),
\]

\[
\kappa(\mu, T) = \frac{\partial^2 P}{\partial \mu^2} = \left( \frac{m}{2\pi} \right)^{3/2} T^{1/2} F(2, 0) \left( \frac{\mu}{T}, \tilde{g}(T) \right),
\]

respectively, where we use the notation \( F^{(i,j)}(x, y) = \delta_i^x \delta_j^y F(x, y) \).

For positive chemical potential, there is a superfluid transition at a temperature \( T_s \). This transition corresponds to a singularity of the scaling function \( F(x, y) \) when \( x = x_c(y) \). It follows that

\[
\frac{\mu}{T_c} = \mathcal{H}(\tilde{g}(T_c)),
\]

with \( \mathcal{H} \) a universal scaling function. Equation (10) implies that \( ma^2 T_c \) is a universal function of \( ma^2 \mu \).

In the superfluid phase, using (8)

\[
n_0(\mu, T) = s^{-d-\epsilon/2} n_0(\mu, s^2 T, \tilde{g}(\mu))
\]

with \( s \sim |\mu|^{-\epsilon} \), one finds that the condensate density satisfies the scaling form

\[
n_0(\mu, T) = \left( \frac{m \mu}{2\pi} \right)^{3/2} \mathcal{I} \left( \frac{T}{\mu}, \tilde{g}(\mu) \right),
\]

with \( \mathcal{I} \) a universal function and \( \tilde{g}(\mu) \) defined by Eq. (8). The superfluid density (or superfluid stiffness \( \rho_s = n_s/m \)) satisfies a similar scaling form

\[
n_s(\mu, T) = \left( \frac{m \mu}{2\pi} \right)^{3/2} \mathcal{J} \left( \frac{T}{\mu}, \tilde{g}(\mu) \right).
\]

Galilean invariance implies that the \( T = 0 \) superfluid density \( n_s(\mu, 0) \) is equal to the fluid density \( \tilde{n}(\mu, 0) \) and is therefore determined by the scaling function \( F \) [Eq. (9)]. The sound mode velocity can be expressed in terms of the compressibility and the superfluid stiffness \( \rho_s = n_s/m \) (see, e.g., Ref. [9]),

\[
c(\mu, T) = \sqrt{\frac{\rho_s(\mu, T)}{\kappa(\mu, T)}}
\]

At zero temperature, since \( n_s = \tilde{n} \), the Bogoliubov sound mode velocity \( c(\mu, 0) \) is equal to the macroscopic sound velocity [10].

### B. Limiting cases

For a three-dimensional Bose gas, the scaling functions can be obtained from perturbation theory (see Appendix A). In this section, we discuss various limiting cases.

#### 1. Dilute classical gas

When the chemical potential is large and negative, \( \mu < 0 \) and \( |\mu| \gg T \), the system behaves as a dilute classical gas and the pressure takes the form

\[
P(\mu, T) = \left( \frac{m}{2\pi} \right)^{3/2} T^{5/2} e^{-|\mu|/T},
\]

which leads to

\[
F(x, y) = e^x \quad \text{for} \quad x < 0 \quad \text{and} \quad |x| \gg 1,
\]

\[
G(x, y) = x^{5/2} e^{1/2} \quad \text{for} \quad x < 0 \quad \text{and} \quad |x| \ll 1.
\]

#### 2. \( T = 0 \) superfluid phase

At low temperatures and positive chemical potential, the scaling functions can be obtained from the Bogoliubov theory [11,12]. At zero temperature,

\[
P(\mu, 0) = \frac{m \mu^2}{8\pi a^2} \left( 1 - \frac{64}{15\pi} \sqrt{\frac{ma^2 \mu}{2\pi}} \right),
\]

\[
\tilde{n}(\mu, 0) = \frac{m \mu}{4\pi a} \left( 1 - \frac{16}{3\pi} \sqrt{\frac{ma^2 \mu}{2\pi}} \right),
\]

\[
\kappa(\mu, 0) = \frac{m \mu}{4\pi a} \left( 1 - \frac{8}{3\pi} \sqrt{\frac{ma^2 \mu}{2\pi}} \right),
\]

\[
n_0(\mu, 0) = \frac{m \mu}{4\pi a} \left( 1 - \frac{20}{3\pi} \sqrt{\frac{ma^2 \mu}{2\pi}} \right),
\]

and \( \rho_s(\mu, 0) = n_s(\mu, 0)/m = \tilde{n}(\mu, 0)/m \). The first term in these equations is usually referred to as the mean-field result and the second one as the Lee-Huang-Yang correction [13,14]. Equations (17)–(20) can be cast in the forms (7), (12), and (13) with

\[
\mathcal{G}(0, y) = \frac{4\pi^{3/2}}{y} \left( 1 - \frac{4\sqrt{2}y}{15\pi^2} \right),
\]

\[
\mathcal{I}(0, y) = \frac{8\pi^{3/2}}{y} \left( 1 - \frac{5\sqrt{2}y}{12\pi^2} \right),
\]

\[
\mathcal{J}(0, y) = \frac{8\pi^{3/2}}{y} \left( 1 - \frac{\sqrt{2}y}{3\pi^2} \right).
\]

From Eqs. (18) and (19), we deduce the expression of the sound mode velocity (14),

\[
c(\mu, 0) = \sqrt{\frac{\mu}{m}},
\]

to leading order in \( ma^2 \mu \).

#### 3. Quantum critical regime \( \mu = 0 \)

At vanishing chemical potential, the condensate density vanishes and the Bogoliubov theory reproduces the free boson result

\[
P(0, T) = -\frac{1}{\beta} \int_{\mathbf{q}} \ln(1 - e^{-\beta q}) = \xi(5/2) \left( \frac{m}{2\pi} \right)^{3/2} T^{5/2},
\]

where \( \xi(x) \) is the Riemann zeta function and \( \xi(5/2) \approx 1.3415 \). Equation (23) implies

\[
\mathcal{F}(0, y) = \xi(5/2) \quad \text{for} \quad y \to 0.
\]
4. Superfluid transition

The Bogoliubov theory correctly describes the ground state and its elementary excitations but fails near the superfluid transition temperature $T_c$. In particular, it predicts a first-order phase transition [15]. The transition temperature can nevertheless be determined from a perturbative approach in the normal phase by considering the self-consistent one-loop correction to the self-energy (self-consistent Hartree-Fock approximation)

$$\mu = \frac{8\pi a}{m} \left( \frac{m T_c}{2\pi} \right)^{3/2},$$

which leads to

$$\mathcal{H}(x) = \frac{\xi(3/2)}{4\pi^{3/2}} x.$$  

(26)

III. LATTICE NPRG

In this section, we briefly review the NPRG approach to the Bose-Hubbard model defined on a cubic lattice [5,6]. The model is defined by the action

$$S = \int_0^\beta d\tau \left\{ \sum_\mathbf{r} \left[ \psi_\mathbf{r}^\dagger \left( \partial_\tau - \mu \right) \psi_\mathbf{r} + \frac{U}{2} (\psi_\mathbf{r}^\dagger \psi_\mathbf{r})^2 \right] ight. $$

$$- t \sum_{\langle \mathbf{r}, \mathbf{r}' \rangle} (\psi_\mathbf{r}^\dagger \psi_\mathbf{r}' + \text{c.c.}) \right\},$$

where $\psi_\mathbf{r}(\tau)$ is a complex field. $\{\mathbf{r}\}$ denotes the $N$ sites of the lattice and $\{\mathbf{r}, \mathbf{r}'\}$ nearest-neighbor sites. $U$ is the onsite repulsion and $t$ the hopping amplitude. We take the lattice spacing as the unit length throughout the paper.

A. Scale-dependent effective action

The NPRG is implemented by considering a family of models with action $S_k = S + \Delta S_k$ indexed by a momentum scale $k$ varying between a microscopic scale $\Lambda$ down to 0 [16,17]. $\Delta S_k$ is a “regulator” term defined by

$$\Delta S_k = \int_0^\beta d\tau \sum_\mathbf{q} \psi_\mathbf{q}^\dagger R_k(\mathbf{q}) \psi_\mathbf{q},$$

(28)

where $\psi_\mathbf{q}(\tau)$ is the Fourier transform of $\psi_\mathbf{r}$ and the sum over $\mathbf{q}$ runs over the first Brillouin zone $[-\pi, \pi]^d$ of the reciprocal lattice. The cutoff function $R_k(\mathbf{q})$ modifies the bare dispersion $\epsilon_q = -2t \sum_{i=1}^d \cos q_i$ of the bosons. In the lattice scheme, $R_k(\mathbf{q})$ is chosen such that the effective (bare) dispersion $\epsilon_q + R_k(\mathbf{q})$ vanishes [18]. The action $S_k = S + \Delta S_k$ then corresponds to the local limit of decoupled sites (vanishing hopping amplitude).

In practice, we choose the cutoff function

$$R_k(\mathbf{q}) = -Z_{A,k} \epsilon_k \text{sgn}(\epsilon_q)(1 - \epsilon_q) \Theta(1 - \epsilon_q),$$

(29)

with $\Lambda = \sqrt{2d}$, $\epsilon_k = k^2$, $\epsilon_q = (2d - |q|)^2 / \epsilon_k$, and $\Theta(x)$ the step function. The $k$-dependent constant $Z_{A,k}$ is defined below ($Z_{A,\Lambda} = 1$). Since $R_{k=0}(\mathbf{q}) = 0$, the action $S_{k=0}$ coincides with the action (27) of the original model. For small $k$, the function $R_k(\mathbf{q})$ gives a “mass” $\sim k^2$ to the low-energy modes $|\mathbf{q}| \lesssim k$ and acts as an infrared regulator as in the standard NPRG scheme [16,17].

The scale-dependent effective action

$$\Gamma_k[\phi^*, \phi] = -\ln Z_k[J^*, J] + \int_0^\beta d\tau \sum_{\mathbf{r}} (J_\mathbf{r}^* \phi_\mathbf{r} + \text{c.c.})$$

$$- \Delta S_k[\phi^*, \phi]$$

(30)

is defined as a (slightly modified) Legendre transform which includes the explicit subtraction of $\Delta S_k[\phi^*, \phi]$. Here, $Z_k[J^*, J]$ is the partition function obtained from the action $S + \Delta S_k$; $J$ is a complex external source which couples linearly to the bosonic field $\phi_\mathbf{r}$, and

$$\phi_\mathbf{r}(\tau) = \langle \psi_\mathbf{r}(\tau) \rangle = \frac{\delta \ln Z_k[J^*, J]}{\delta J_\mathbf{r}^*(\tau)}$$

(31)

the superfluid order parameter. The variation of the effective action with $k$ is governed by Wetterich’s equation [19]

$$\partial_k \Gamma_k[\phi^*, \phi] = \frac{1}{2} \text{Tr} \left\{ \partial_k R_k(\Gamma_k^{(2)}) [\phi^*, \phi] + R_k \right\},$$

(32)

where $\Gamma_k^{(2)}$ is the second-order functional derivative of $\Gamma_k$. In Fourier space, the trace in Eq. (32) involves a sum over momenta and frequencies as well as the two components of the complex field $\phi$.

We are primarily interested in two quantities. The first one is the effective potential defined by

$$V_k(n) = \frac{1}{\beta N} \Gamma_k[\phi^*, \phi] |_{\phi \text{ const}},$$

(33)

where $\phi$ is a constant (uniform and time-independent) field. The U(1) symmetry of the action implies that $V_k(n)$ is a function of $n = |\phi|^2$. Its minimum determines the condensate density $n_{0,k}$ and the thermodynamic potential (per site) $V_0,k = V_k(n_{0,k})$ in the equilibrium state.

The second quantity of interest is the two-point vertex

$$\Gamma_{k,i,j}(\mathbf{r} - \mathbf{r}', \tau - \tau'; \phi) = \left. \frac{\delta^{(2)} \Gamma_k[\phi]}{\delta \phi_i(\tau) \delta \phi_j(\tau')} \right|_{\phi \text{ const}},$$

(34)

which determines the one-particle propagator $G_k = -\Gamma_k^{(2)-1}$ and enters the flow equation (32). Here, the indices $i, j$ refer to the real and imaginary parts of $\phi$:

$$\phi_\mathbf{r}(\tau) = \frac{1}{\sqrt{2}} [\phi_1(\tau) + i \phi_2(\tau)].$$

(35)

Because of the U(1) symmetry of the action (27), the two-point vertex in a constant field takes the form [9]

$$\Gamma_{k,i,j}(q; \phi) = \delta_{ij} \Gamma_{A,k}(q; n) + \phi_i \phi_j \Gamma_{R,k}(q; n) + \epsilon_{ij} \Gamma_{C,k}(q; n),$$

(36)

in Fourier space, where $q = (\mathbf{q}, i\omega)$, $\omega$ is a Matsubara frequency, and $\epsilon_{ij}$ the antisymmetric tensor. For $q = 0$, we can relate $\Gamma_k^{(2)}$ to the derivative of the effective potential

$$\Gamma_{k,i,j}(q = 0; \phi) = \frac{\partial^2 V_k(n)}{\partial \phi_i \partial \phi_j} = \delta_{ij} V'_k(n) + \phi_i \phi_j V''_k(n).$$

(37)
so that
\[ \Gamma_{A,k}(q = 0; n) = V_k'(n), \quad \Gamma_{B,k}(q = 0; n) = V_k''(n), \quad \Gamma_{C,k}(q = 0; n) = 0. \] (38)

B. Initial conditions
Since the action \( S + \Delta S_{\lambda} \equiv S_{\text{loc}} \) corresponds to the local limit, the initial value of the effective action reads as
\[ \Gamma_{\lambda}[\phi^*, \phi] = \Gamma_{\text{loc}}[\phi^*, \phi] + \int_0^\beta d\tau \sum_q \phi^*(q) \phi(q), \] (39)
where \( \Gamma_{\text{loc}}[\phi^*, \phi] \) is the effective action in the local limit (\( t = 0 \)). It is not possible to compute the functional \( \Gamma_{\text{loc}}[\phi^*, \phi] \) for arbitrary time-dependent fields [6]. One can, however, easily obtain the effective potential \( V_{\text{loc}}(n) \) and the two-point vertex \( \Gamma_{\text{loc}}^{(2)} \) in a time-independent field \( \phi \). These quantities are sufficient to specify the initial conditions of the flow within the approximations discussed in the following.

The initial effective action \( \Gamma_{\lambda} \) [Eq. (39)] treats the local fluctuations exactly but includes the intersite hopping term at the mean-field level, thus reproducing the strong-coupling random-phase approximation (RPA) [20–24].

C. Approximate solutions of the NPRG equations
To solve the NPRG equations, we expand the effective potential about its minimum,
\[ V_k(n) = V_{0,k} + \delta_k(n - n_{0,k}) + \frac{\lambda_k}{2}(n - n_{0,k})^2, \] (40)
where
\[ \delta_k = \frac{\partial V_k}{\partial n} \bigg|_{n_{0,k}}, \quad \lambda_k = \frac{\partial^2 V_k}{\partial n^2} \bigg|_{n_{0,k}}. \] (41)

\( V_{0,k} \) determines the thermodynamic potential per site and in turn the pressure \( P(\mu, T) = -V_{0,k} - d \). We also use a derivative expansion where the two-point vertex \( \Gamma_{\lambda}^{(2)}(q) \equiv \Gamma_{\text{loc}}^{(2)}(q; n_{0,k}) \) in the equilibrium state is defined by
\[ \Gamma_{A,k}(q) = Z_{A,k}(q + 2d \ell) + V_{A,k} \partial^2 + \delta_k, \quad \Gamma_{B,k}(q) = \lambda_k, \quad \Gamma_{C,k}(q) = Z_{C,k} \omega. \] (42)

The initial values \( Z_{A,k}, V_{A,k}, Z_{C,k}, \delta_k, \) and \( \lambda_k \) are deduced from \( \Gamma_{\text{loc}}^{(2)} \) and \( V_{\text{loc}}(n) \). The flow equations of \( Z_{A,k}, V_{A,k}, Z_{C,k}, \delta_k, \) and \( \lambda_k \) are then obtained from the exact flow equation (32) within a simplified Blaizot–Méndez-Galain–Wschebor scheme [25,26]. We refer to Ref. [6] for a detailed discussion.

D. Infrared behavior
The infrared behavior can be obtained from the action
\[ \Gamma_{\kappa}[\phi^*, \phi] = \int_0^\beta d\tau \int d^3 r \left[ \phi^*(Z_{C,k} \partial_r - V_{A,k} \partial^2 + Z_{A,k} \partial^2 \right. \right. \]
\[ - Z_{A,k} \partial^2 \right] \phi + \frac{\lambda_k}{2}(n - n_{0,k})^2 + V_{0,k}. \] (43)

Since we are interested in the low-energy limit, we consider the continuum limit where \( r \) becomes a continuous variable.

Higher-order (in derivative or field) terms neglected in (43) give subleading contributions to the infrared behavior. Most physical quantities of interest can be directly deduced from Eq. (43) [6]. The pressure is given by
\[ P(\mu, T) = -V_{0,k} - d. \] (44)

In the superfluid phase, the superfluid stiffness can be expressed as
\[ \rho_s(\mu, T) = 2t Z_{A,k} n_{0,k} \] (45)
and the sound velocity reads as
\[ c(\mu, T) = \sqrt{\frac{\rho_s(\mu, T)}{\kappa(\mu, T)}}, \] (46)
where \( \kappa = \partial^2 P / \partial \mu^2 \) is obtained from Eq. (44).

IV. UNIVERSAL THERMODYNAMICS NEAR THE MOTT TRANSITION

In this section, we first discuss the QCP between the superfluid phase and the Mott insulator. We show that elementary excitations are quasiparticles with spectral weight \( Z_{\text{qp}}, \) effective mass \( m^*, \) and effective “scattering” length \( a^* \). \( Z_{\text{qp}}, m^*, \) and \( a^* \) are computed as a function of \( t / U \) using the NPRG equations. We then verify that near the generic Mott transition, thermodynamics quantities, as obtained from the NPRG approach, can be expressed in terms of the universal scaling functions introduced in Sec. II.

A. Quantum critical point
At the quantum critical point \( (\mu = \mu_c, T = 0) \) between the superfluid and Mott-insulating phases, the effective action \( \Gamma \equiv \Gamma_{\kappa=0} \) [Eq. (43)] takes the form
\[ \Gamma[\phi^*, \phi] = \int_0^\beta d\tau \int d^3 r \left[ \phi^*(Z_{C,k} \partial_r - Z_{A,k} \partial^2) \phi + \frac{\lambda}{2} |\phi|^4 \right] \] (47)
up to a constant term \( \beta N V_0 \) and neglecting higher-order (in field and derivative) terms. Equation (47) is valid at a generic QCP where the transition is driven by a density change. At a multicritical point, where the transition takes place at fixed (commensurate) density, \( Z_C \) vanishes and the leading time-derivative term \( -V_0 \partial^2 \phi / \partial \tau^2 \) must be included in the effective action [5,6].

From Eq. (47), we can identify the elementary excitations at the QCP. On the lower part of the transition line (for a given Mott lobe), \( Z_C \) is negative and it is convenient to perform a particle-hole transformation \( \phi \leftrightarrow \phi^* \) [which changes the sign of the \( \partial_r \) term in Eq. (47)]. We can then define a quasiparticle field
\[ \phi(r, \tau) = \sqrt{Z_C} \phi(r, \tau), \] (48)
and rewrite the effective action as
\[ \Gamma[\phi^*, \phi] = \int_0^\beta d\tau \int d^3 r \left[ \phi^*(\partial_r - \frac{\nabla^2}{2m^*}) \phi + \frac{1}{2} \frac{4\pi a^*}{m^*} |\phi|^4 \right]. \] (49)
where

\[ m^{*} = \frac{|Z_C|}{2\pi Z_A} = \frac{m}{|Z_C|}Z_A, \quad a^{*} = \frac{m^{*}\lambda}{4\pi Z_C}, \] (50)

with \( m = 1/2t \) the effective mass of the free bosons moving in the lattice. We deduce from Eqs. (48) and (49) that elementary excitations are quasiparticles with mass \( m^{*} \) and spectral weight

\[ Z_{qp} = |Z_C|^{-1}, \] (51)

They are particlelike if \( Z_C > 0 \) and holelike if \( Z_C < 0 \). The effective interaction between two quasiparticles is determined by the effective “scattering length” \( a^{*} \).

The quantum phase transition at \( \mu = -2dt \) between the superfluid phase and the vacuum (which can be seen as a Mott insulator with vanishing density) is a particular case of a superfluid–Mott-insulator transition which differs from the superfluid-vacuum transition discussed in Sec. II A only by the presence of the lattice. In this case, \( Z_A = Z_C = 1 \) (the single-particle propagator is not renormalized \([3,4]\)), so that \( Z_{qp} = 1 \) and \( m^{*} = m = 1/2t \). Furthermore, the interaction constant \( \lambda = 4\pi a/m = 8\pi ta \) can be calculated analytically and related to the scattering length

\[ a = \frac{1}{8\pi(t/U + A)}, \quad A \simeq 0.1264 \] (52)

of the bosons moving in the lattice \([6]\), which gives \( a^{*} = a \).

For a generic QCP between the superfluid phase and a Mott-insulating phase with nonzero density (\( \bar{n} = 1, 2, 3, \ldots \)), the values of \( Z_{qp}, m^{*} \), and \( a^{*} \) can be obtained from the numerical solution of the NPRG equations. Figures 2 and 3 show \( Z_A, Z_C, \lambda \) and \( Z_{qp}, m^{*}, a^{*} \) as a function of \( t/U \) for the transition between the superfluid phase and the Mott insulator with density \( \bar{n} = 1 \). The vanishing of \( Z_C \) at the multicritical point implies that \( m^{*} \) vanishes while \( Z_{qp} \) and \( a^{*} \) diverge as we approach the tip of the Mott lobe. In addition to the NPRG results, in Fig. 3 we show \( m^{*} \) obtained from quantum Monte Carlo (QMC) simulations \([27]\) as well as \( m^{*} \) and \( Z_{qp} \) obtained from the strong-coupling random-phase approximation (RPA) (see Appendix B). The RPA value for the hopping amplitude at the tip of the Mott lobe, \( t/U \approx 0.0286 \), is far away from the QMC \( (t/U = 0.034083) \) \([27]\) or NPRG \( (t/U = 0.0339) \) \([28]\) results. Nevertheless, the RPA predictions for the quasiparticle weight \( Z_{qp} \) and the effective mass \( m^{*} \), when plotted as a function of \( t/t_c \), are in good agreement with the NPRG and QMC results (Fig. 3). As expected, the results for the lower part of the transition line are trivial in the limit \( t \to 0 \): \( Z_{qp} = m^{*}/m = a^{*}/a = 1 \) (they are simply obtained by considering the motion of a hole in a Mott insulator with one boson per site).

In Fig. 4, we show \( Z_{qp}, m^{*} \), and \( a^{*} \) as a function of \( t/t_c \) for the transition between the superfluid phase and the Mott insulator with density \( \bar{n} = 2 \). The results are similar to the case of the transition to the first Mott lobe \( (\bar{n} = 1) \), but the behavior for \( t \to 0 \) is different. The limiting values of the effective mass and quasiparticle weight are given by the strong-coupling RPA (see Appendix B)

\[ \lim_{t/U \to 0} Z_{qp} = \lim_{t/U \to 0} m^{*} = \begin{cases} \bar{n} & \text{(lower branch)}, \\ \bar{n} + 1 & \text{(upper branch)}. \end{cases} \] (53)
where \( \bar{n} \) denotes the (commensurate) density of the Mott insulator and we distinguish between the upper \((\mu \simeq U(\bar{n})\) and lower \([\mu \simeq U(\bar{n} - 1)]\) branches of the transition line.

Since \( m^*/m \) and \( a^*/a \) are typically of order one (except close to the Mott lobe tip), the characteristic energy scale \( 1/m^*a^{*2} \) below which the physics is universal is roughly set by the hopping amplitude \( t \). As we approach the tip of the Mott lobe (point C in Fig. 1), \( m^*a^{*2} \) diverges and the energy scale \( 1/m^*a^{*2} \) vanishes. The low-energy physics is then controlled by the multicritical point.

**B. Universal thermodynamics**

Since the superfluid–Mott-insulator transition belongs to the dilute Bose gas universality class, near the QCP the thermodynamics can be expressed in terms of the universal scaling functions introduced in Sec. II as well as the nonuniversal parameters \( m^* \) and \( a^* \). To ensure that there is no other nonuniversal parameter, we must verify that the chemical potential (or, more precisely, \( \delta \mu = \mu - \mu_c \)) couples to the elementary excitations with no additional renormalization.

Slightly away from the QCP, the shift \( \delta \mu = \mu - \mu_c \) in chemical potential implies a change

\[
\delta S = -\delta \mu \int_0^\beta d\tau \sum_r \psi^* r \psi_r
\]  

in the action. To lowest order in \( \delta \mu \), \( \delta S \) induces a correction

\[
\delta \Gamma[\phi^*,\phi] = -Z_\mu \delta \mu \int_0^\beta d\tau \int d^3r \phi^* \phi
\]

(55)

to the effective action (47) at the QCP, where \( Z_\mu \) is a renormalization factor. Using the Ward identity \( Z_\mu \) acts as a chemical potential for the elementary excitations at the QCP [29]. This implies that \( \pm \delta \mu / T \) will enter scaling functions with no additional scale factor. This result agrees with general considerations on the scaling of conserved densities near a continuous quantum phase transition [30].

Near the superfluid–Mott-insulator transition we can therefore write the pressure as

\[
P(\mu,T) = P_c + \bar{n}_c \delta \mu + \left( \frac{m^*}{2\pi} \right)^{3/2} T^{5/2} \mathcal{F} \left( \pm \frac{\delta \mu}{T}, \tilde{g}(T) \right) \]

(57)

or

\[
P(\mu,T) = P_c + \bar{n}_c \delta \mu + \left( \frac{m^*}{2\pi} \right)^{3/2} |\delta \mu|^{5/2} \tilde{g} \left( \pm \frac{T}{\delta \mu}, \tilde{g}(\delta \mu) \right),
\]

(58)

where

\[
\tilde{g}(\epsilon) = 8\pi \sqrt{2m^*a^{*2}|\epsilon|}
\]

(59)

is obtained from Eq. (8) by replacing \( m \) and \( a \) by \( m^* \) and \( a^* \). The \( + \) (–) sign in Eqs. (57) and (58) corresponds to particle (hole) doping of the Mott insulator [i.e., the upper (lower) part of the transition line]. Universality arguments imply that the singular part of the pressure can be expressed in terms of the scaling function \( \mathcal{F} \) but do not allow us to determine the regular part. To obtain the latter, we note that the compressibility \( \kappa = \beta^2 P/\beta \mu^2 \) vanishes in the \( T = 0 \) Mott insulator and has therefore no regular part,

\[
\kappa(\mu,T) = \left( \frac{m^*}{2\pi} \right)^{3/2} T^{1/2} \mathcal{F}^{(2,0)} \left( \pm \frac{\delta \mu}{T}, \tilde{g}(T) \right)
\]

(60)
[see Eq. (9)]. Integrating this equation twice with respect to \( \mu \) yields Eq. (57) with \( P_c \) the value of the pressure at the QCP and \( \bar{n}_c \), the density at the QCP [31].

The results obtained from a numerical solution of the NPRG equations show that near the superfluid–Mott-insulator transition, the pressure can be expressed in terms of the universal scaling function \( \mathcal{F} \) discussed in Sec. II. In the dilute classical regime, \( \text{sgn}(Z_C)\delta \mu < 0 \) and \( |\delta \mu| \gg T \), our results
are compatible with the expected result

$$P(\mu, T) = P_c + \bar{n}_c \delta \mu + \left( \frac{m_*}{2\pi} \right)^{3/2} T^{5/2} e^{-|\delta \mu|/T}$$  \hspace{1cm} (61)$$

[see Eq. (15)]. However, a precise comparison is prevented by numerical difficulties due to the extremely small values of the pressure in this regime. The finite-temperature pressure at point B in Fig. 1 is shown in Fig. 5. We find a very good agreement with

$$P(\mu_c, T) = P_c + \kappa(\mu, T)$$  \hspace{1cm} (62)$$

below a crossover temperature scale $T \sim 2T_c$. Figure 6 shows the $T = 0$ pressure at fixed $t/U$ and for a density $\bar{n}$ varying between 0 and 1 (see the dotted line in Fig. 1). Near the Mott-insulating phases ($\bar{n} \simeq 0$ or 1), for $|\delta \mu| \lesssim t$, there is a very good agreement between the NPRG result and the universal form

$$P(\mu, 0) = P_c + \bar{n}_c \delta \mu + \frac{m^*(\delta \mu)^2}{8\pi a^*} \left( 1 - \frac{64}{15\pi} \frac{m^* a^{*2}|\delta \mu|}{|\delta \mu|^3} \right).$$  \hspace{1cm} (63)$$

It should be noted that the agreement is better with the “Lee-Huang-Yang correction” [last term of Eq. (63)] than without. Differentiating (63) with respect to $\mu$, we obtain

$$\bar{n}(\mu, 0) = \bar{n}_c + \frac{m^* \delta \mu}{4\pi a^*} \left( 1 - \frac{16}{3\pi} \sqrt{m^* a^{*2}|\delta \mu|} \right),$$  \hspace{1cm} (64)$$

$$\kappa(\mu, 0) = \frac{m^*}{4\pi a^*} \left( 1 - \frac{8}{\pi} \sqrt{m^* a^{*2}|\delta \mu|} \right).$$  \hspace{1cm} (65)$$

The condensate density $n_0(\mu, T)$ in the superfluid phase can be expressed in terms of the scaling function $\mathcal{I}$ [Eq. (12)]. However, since only the coherent part of the excitations (i.e., the quasiparticles) condenses, Eq. (12) can be used for the condensate density $|\phi|^2$ of the quasiparticles while $|\phi|^2 = Z_{sp}|\hat{\phi}|^2$, which leads to

$$n_0(\mu, T) = Z_{sp} \left( \frac{m^* |\delta \mu|}{2\pi} \mathcal{I} \left( \frac{T}{|\delta \mu|} \right) \right)^{3/2}$$  \hspace{1cm} (66)$$

near the superfluid–Mott-insulator transition. The fact that $n_0(\mu, T)$, contrary to other physical quantities discussed in this section, depends on the quasiparticle weight can be understood by noting that $\phi$ is not invariant in the local gauge transformation (C3) and therefore not “protected” by the Ward identity (C4). At zero temperature,

$$n_0(\mu, 0) = Z_{sp} \frac{m^* |\delta \mu|}{4\pi a^*} \left( 1 - \frac{20}{3\pi} \sqrt{m^* a^{*2}|\delta \mu|} \right).$$  \hspace{1cm} (67)$$

where $m^*|\delta \mu|/4\pi a^* \simeq |\bar{n} - \bar{n}_c|$ is the density of excess particles (or holes) with respect to the commensurate density $\bar{n}_c$ of the Mott insulator. The $T = 0$ condensate density along the dotted line in Fig. 1 is shown in Fig. 7. Near the Mott-insulating

![FIG. 5](image_url) **FIG. 5.** (Color online) Pressure $P(\mu_c, T)$ vs temperature $T$ ($t/U = 0.02$ and $\mu_c/U \simeq 0.15$ (point B in Fig. 1)). The dashed (green) line corresponds to Eq. (62). The inset shows a log-log plot and the $T^{5/2}$ dependence of $P(\mu_c, T) - P_c$. The inset shows a log-log plot and the $T^{5/2}$ dependence of $P(\mu_c, T) - P_c$.

![FIG. 6](image_url) **FIG. 6.** (Color online) Zero-temperature pressure $P(\mu, 0)$ vs chemical potential $\mu$ along the dotted line in Fig. 1 (the inset shows the density $\bar{n} = \partial P/\partial \mu$). The bottom figures show the behavior near the Mott-insulating phases $\bar{n} = 0$ and 1. The dashed (green) line corresponds to Eq. (63) and the dashed-dotted (blue) one to the “mean-field” result $P = P_c + \bar{n}_c \delta \mu + (\delta \mu)^2 m^*/8\pi a^*$.

![FIG. 7](image_url) **FIG. 7.** (Color online) Condensate density $n_0(\mu, 0)$ vs $\mu$ along the dotted line in Fig. 1. The insets show the behavior near the Mott-insulating phases $\bar{n} = 0$ and 1. The dashed (green) line corresponds to Eq. (63) and the dashed-dotted (blue) one to the “mean-field” result $n_0 = Z_{sp} m^* |\delta \mu|/4\pi a^*$.

043624-8
phases $\bar{n}_c = 0$ and $1$, we find a very good agreement with Eq. (67).

The superfluid stiffness can be expressed using the scaling function $\mathcal{J}$ [Eq. (13)]:

$$\rho_s(\mu, T) = \sqrt{m^*} \left( \frac{|\delta \mu|}{2\pi} \right)^{3/2} \mathcal{J} \left( \frac{T}{|\delta \mu|} \tilde{g}(\delta \mu) \right).$$

Using the results of Sec. II B, we obtain

$$\rho_s(\mu, 0) = \frac{|\delta \mu|}{4\pi a^*} \left[ 1 - \frac{16}{3\pi} \sqrt{m^* a^2 |\delta \mu|} \right] = \frac{|\bar{n}(\mu, 0) - \bar{n}_c|}{m^*}.$$  \hspace{1cm} (69)

again in very good agreement with the NPRG approach (Fig. 8). $\rho_s$, contrary to $n_0$, is independent of the quasiparticle weight $Z_{\text{qp}}$. This follows from the fact that the superfluid stiffness can be related to the current-current density correlation function [32], which is a gauge-invariant quantity. As a result, the ratio between condensate density and superfluid stiffness,

$$\frac{n_0(\mu, 0)}{m^* \rho_s(\mu, 0)} = Z_{\text{qp}}$$  \hspace{1cm} (70)

(to leading order in $m^* a^2 |\delta \mu|$), explicitly depends on the quasiparticle weight while it is equal to unity in a dilute Bose gas.

From Eqs. (65) and (69), we deduce

$$c(\mu, 0) \simeq \sqrt{\frac{\rho_s(\mu, 0)}{\kappa(\mu, 0)}} \left( \frac{|\delta \mu|}{m^*} \right)$$  \hspace{1cm} (71)

to leading order in $m^* a^2 |\delta \mu|$. As the condensate density $n_0$ and the superfluid stiffness $\rho_s$, $c$ is related to the density of excess particles (or holes) $|\bar{n} - \bar{n}_c|$ rather than the full density $\bar{n}$. The NPRG results show that Eq. (71) is very well satisfied near the Mott transition (Fig. 9).

The superfluid transition temperature is determined by the scaling function $\mathcal{H}$,

$$\left( \frac{|\delta \mu|}{T_c} \right) = \mathcal{H}(\tilde{g}(T_c)),$$  \hspace{1cm} (72)

where $H$ is the universal scaling function introduced in Sec. II A. Using (26), we then obtain

$$T_c = \frac{2\pi}{m^*} \left( \frac{m^* |\delta \mu|}{8\pi \zeta(3/2) a^*} \right)^{2/3} = \frac{2\pi}{m^*} \left( \frac{|\bar{n} - \bar{n}_c|}{2\zeta(3/2)} \right)^{2/3}$$  \hspace{1cm} (73)

(to leading order in $m^* a^2 |\delta \mu|$) near the $T = 0$ Mott transition, in very good agreement with the NPRG results (Fig. 10).

C. RG flows and approach to universality

Figure 11 shows the flow of the coupling constants $Z_{C, k}$ and $\lambda_k$ in the zero-temperature superfluid phase near a QCP. Exactly at the QCP ($\delta \mu = 0$), one can clearly distinguish two regimes: (i) a high-energy (or short-distance) regime $k \gtrsim k_x$, where lattice effects are important and the dimensionless coupling constant [6]

$$\tilde{\lambda}_k = \frac{k}{Z_{C,k} Z_{\alpha,k} \lambda_k}$$  \hspace{1cm} (74)

is large, (ii) a weak-coupling (“Bogoliubov”) regime $k \lesssim k_x$ where $\tilde{\lambda}_k \ll 1$ and the flow is governed by the Gaussian fixed point $\tilde{\lambda}_k = 0$: $\lambda_{C,k}$, $Z_{C,k}$, and $Z_{\alpha,k}$ are then nearly equal to their fixed-point values [Eqs. (50)], while $\tilde{\lambda}_k \propto k$ vanishes in agreement with its scaling dimension $[\tilde{\lambda}_k] = 4 - d - z = -1$ at the Gaussian fixed point ($d = 3$ and $z = 2$). In the momentum regime $|q| \lesssim k_x$, the quasiparticles with mass $m^*$
and scattering length $a$ introduced in Sec. IV A are well defined and the physics becomes universal. The crossover scale $k_x$ between the two regimes is typically of the order of $\Lambda = \sqrt{\lambda/a}$ (except close to the tip of the Mott lobe), these conditions can be rewritten as

$$\sqrt{\lambda/a} \ll 1.$$  

(75)

In the low-energy limit, the system behaves as a gas of weakly interacting quasiparticles if the dimensionless coupling constant

$$\tilde{\lambda}_{kh} = \frac{k_h}{Z_{C,kh} Z_{A,kh}} \lambda_{kh} \simeq 8\pi k_h a^*$$

(79)

is small. The last result in Eq. (79) is obtained using $k_h \ll k_x$, which allows us to approximate $Z_{C,kh}$, $Z_{A,kh}$, and $\lambda_{kh}$ by their $k = 0$ values. Since $k_x \sim a^{-1} \sim 1$, universality ($k_h \ll k_x$) implies weak coupling ($k_h a^* \ll 1$). Using Eq. (64), the weak-coupling and universality condition $k_h a^* \ll 1$ [Eq. (77)] can be rewritten as

$$\sqrt{|\tilde{n} - \tilde{n}_c| a^{\alpha \delta}} \ll 1.$$  

(80)

Equation (80) is similar to the usual condition for a boson gas to be dilute except that it involves the excess density of particles (or holes) $|\tilde{n} - \tilde{n}_c|$ (with respect to the commensurate density of the Mott insulator) rather than the full density $\tilde{n}$ of the fluid.

For $k \lesssim k_h$, $\lambda_h$ and $Z_{C,kh}$ depart from their fixed-point values at $\delta \mu = 0$ (Fig. 11) and vanish logarithmically below a “Ginzburg” momentum scale $k_G$ which is exponentially small at weak coupling ($\tilde{\lambda}_{kh} \ll 1$). In a dilute Bose gas, the Ginzburg scale manifests itself by the appearance of infrared divergences in the perturbation theory about the Bogoliubov approximation. Although these divergences cancel out for thermodynamic quantities, they do have a physical origin: they result from the coupling between longitudinal and transverse (phase) fluctuations and lead to a divergence of the longitudinal susceptibility, a general phenomenon in systems with a broken continuous symmetry [33]. For $k \sim k_G$, the RG flow crosses over to a “Goldstone” regime where the physics is dominated by phase fluctuations. We refer to Refs. [9,34,35] for a detailed discussion of the infrared behavior in the superfluid phase. The various regimes of the RG flow are summarized in Fig. 12.

V. EXPERIMENTAL DISCUSSION

Although cold gases are inhomogeneous and of finite size due to the harmonic confining potential, using a local-density approximation it is possible to deduce the equation of state $P(\mu, T)$ of the infinite homogeneous gas (with uniform density) from the measured in situ density distribution [36,37]. On the basis of this method, the equation of state of the two- and three-dimensional (homogeneous) Bose gas has been experimentally determined [38–40]. Recently, the same method has been used to obtain the equation of state of...
a two-dimensional Bose gas in an optical lattice near the superfluid-vacuum transition [41].

For a three-dimensional Bose gas in an optical lattice near the superfluid–Mott-insulator transition, the crossover length scale $k_\text{F}^{-1}$ beyond which the physics becomes universal (i.e., controlled by quasiparticles with mass $m^*$ and scattering length $a^*$) is typically of the order of a few lattice spacings (see the discussion in Sec. IV C). This length scale is much smaller than the characteristic length scale of the confining trap, which implies that the local-density approximation is justified in the low-energy (universal) regime. The experimental method used to obtain the equation of state $P(\mu, T)$ of a Bose gas near the superfluid-vacuum transition [41] can therefore also be used to determine the thermodynamics near the superfluid–Mott-insulator transition. This opens up the possibility to test the universality class of the generic three-dimensional Mott transition and the predictions of the NPRG approach regarding the values of $Z_{qg}$, $m^*$, and $a^*$. A measurement of the temperature dependence of the pressure in the quantum critical regime at $\delta \mu = 0$ [Eq. (62)] would directly provide us with the value of the effective mass $m^*$. Quite interestingly, $m^*$ strongly varies with both the ratio $t/U$ and the commensurate value of the density in the Mott insulator [Eq. (53)]. Measuring the scattering length $a^*$ and the quasiparticle weight $Z_{qg}$ is more challenging as it would require us to reach temperatures much smaller than the crossover temperature $T \sim 2t$ below which the thermodynamics becomes universal, which is not possible yet in actual experiments.

VI. CONCLUSION

We have presented a detailed study of the thermodynamics of a Bose gas near the generic (density-driven) Mott transition in the framework of the Bose-Hubbard model. In the critical regime, the physics is governed by weakly interacting quasiparticles with quasiparticle weight $Z_{qg}$, effective mass $m^*$, and “scattering length” $a^*$. Thermodynamic quantities can be expressed using the universal scaling functions of the dilute Bose gas universality class. They are independent of the quasiparticle weight and the only nonuniversal parameters entering the scaling functions are $m^*$ and $a^*$. A notable exception is the condensate density $n_0$, which is proportional to $Z_{qg}$, thus allowing us to determine the quasiparticle weight from a thermodynamic measurement once $m^*$ and $a^*$ are known. The NPRG enables us to compute $Z_{qg}$, $m^*$, and $a^*$ as a function of $t/U$. We find that the strong-coupling RPA, although rather inaccurate to determine the phase diagram, gives reliable estimates of $Z_{qg}$, $m^*$, and $a^*$ as a function of $t/t_c$ (with $t_c$ the value of the hopping amplitude at the tip of the Mott lobe). Finally, we have discussed to what extent the universality class of the generic three-dimensional Mott transition and the NPRG predictions regarding the nonuniversal parameters $m^*$ and $a^*$ could be experimentally verified (Sec. V).

ACKNOWLEDGMENT

We would like to thank B. Capogrosso-Sansone for providing us with the QMC data [27] shown in Fig. 3.

APPENDIX A: PERTURBATIVE CALCULATION OF SCALING FUNCTIONS

In this appendix, we briefly review the perturbative calculation of the universal scaling functions of the three-dimensional dilute Bose gas universality class (Sec. II B). At low temperatures and positive chemical potential, the scaling functions can be obtained from a one-loop calculation (Bogoliubov theory). To organize the loop expansion [42], we introduce a parameter $l$ (which will eventually be set to 1) and consider the partition function

$$Z[J^*, J] = \int D[\psi^*, \psi] e^{-\frac{1}{\hbar} S - \int d^3r (J^* \psi + c.c.)}$$

in the presence of a complex external source $J$. The superfluid order parameter is defined by

$$\phi(\mathbf{r}, \tau) = \int \frac{d\mathbf{p}}{(2\pi)^3} \frac{1}{2} \delta \ln Z[J^*, J] \phi(\mathbf{r}, \tau) = \frac{1}{l} \int \frac{d\mathbf{r}}{l} \int d^3r (J^* \phi + c.c.).$$

We now introduce the effective action

$$\Gamma[\phi^*, \phi] = -\frac{1}{l} \ln Z[J^*, J] + \int_0^\beta d\tau \int d^3r (J^* \phi + c.c.),$$

defined as the Legendre transform of the thermodynamic potential $-l^{-1} \ln Z[J^*, J]$. The loop expansion is an expansion in $1/l$. To one-loop order,

$$\Gamma[\phi^*, \phi] = S[\phi^*, \phi] + \frac{1}{2l} \text{Tr} \ln \left( -\mathcal{G}_c^{-1}[\phi^*, \phi]\right) + O(l^{-2}),$$

where $\mathcal{G}_c[\phi^*, \phi]$ is the classical propagator

$$\mathcal{G}_c[x, x'; \phi^*, \phi] = -\left( \begin{array}{cc} \frac{\partial^2 S}{\partial \phi^*(x) \partial \phi(x')} & \frac{\partial^2 S}{\partial \phi^*(x) \partial \phi(x')} \\ \frac{\partial^2 S}{\partial \phi(x) \partial \phi^*(x')} & \frac{\partial^2 S}{\partial \phi(x) \partial \phi^*(x')} \end{array} \right)$$

we use the notation $x = (\mathbf{r}, \tau)$ and $x' = (\mathbf{r}', \tau')$.

All thermodynamic quantities can be obtained from the effective potential defined by

$$V(n) = \frac{1}{\beta V} \Gamma[\phi^*, \phi]|_{\phi, \text{const}}$$

($\beta$ denotes the volume of the system), where $\phi$ is a constant (uniform and time-independent) field. The $U(1)$ symmetry of the action (27) implies that $V(n)$ is a function of the condensate density $n = |\phi|^2$. The minimum of the effective potential determines the condensate density $n_0$ and the thermodynamic potential $V_0 = V(n_0)$ per unit volume in the equilibrium state. The pressure is then given by

$$P(\mu, T) = -V_0.$$  

To compute the effective potential to one-loop order, we need to evaluate the trace in Eq. (A4) with the classical propagator $\mathcal{G}_c$ evaluated in a constant field,

$$\mathcal{G}_c^{-1}(q; \phi^*, \phi) = \begin{pmatrix} i\omega_n - \xi_q - 2g|\phi|^2 & -g\phi^2 \\ -g\phi^* \phi & -i\omega_n - \xi_q - 2g|\phi|^2 \end{pmatrix},$$

043624-11
where \( \omega_n = n2\pi/\beta \) (n integer) is a bosonic Matsubara frequency, \( \xi_q = \epsilon_q - \mu \), and \( \epsilon_q = q^2/2m \).

1. Zero temperature

Let us first consider the zero-temperature limit. Performing the trace over Matsubara frequencies [43], we obtain

\[
V(n) = -\mu n + \frac{g}{2} n^2 + \frac{1}{2\beta} \int_q (E_q - \xi_q - 2gn) + O(l^{-2}),
\]

(A9)

where \( \int_q = \int d^3q/(2\pi)^3 \) and

\[
E_q = [(\xi_q + 2gn)^2 - (gn)^2]^{1/2}.
\]

(A10)

The condensate density \( n_0 \) in the equilibrium state is obtained from \( V(n_0) = 0 \), i.e.,

\[
n_0 = \frac{\mu}{g} - \frac{1}{2\beta} \int_q \left[ \frac{1}{E_q} (2\xi_q + 3gn_0 - 2) \right] + O(l^{-2}),
\]

(A11)

where \( E_q \) is defined by Eq. (A10) with \( n = n_0 \).

Setting \( n_0 = \mu/g \) in the \( O(1/l) \) term, we obtain the effective potential

\[
V_0 = -\frac{\mu^2}{2g} + \frac{1}{2\beta} \int_q (E_q - \epsilon_q - \mu) + O(l^{-2}),
\]

(A12)

where \( E_q = \sqrt{\epsilon_q (\epsilon_q + 2\mu)} \). To eliminate the dependence on the momentum cutoff \( \Lambda \), we introduce the \( s \)-wave scattering length \( a \),

\[
\frac{m}{4\pi a} = \frac{1}{g} + \int_q \frac{\Theta(\Lambda - |q|)}{2\epsilon_q},
\]

(A13)

and rewrite \( V_0 \) as

\[
V_0 = -\frac{m\mu^2}{8\pi a} + \frac{\mu^2}{4} \int_q \left( \frac{1}{\epsilon_q} - \frac{1}{E_q} \right)
\]

\[
+ \frac{1}{2} \int_q \left( E_q - \epsilon_q - \mu + \frac{\mu^2}{2E_q} \right),
\]

(A14)

setting \( l = 1 \). The sums over \( q \) are now convergent and we can take the infinite cutoff limit \( \Lambda \to \infty \) with \( a \) fixed. Using

\[
\int_q \left( \frac{1}{\epsilon_q} - \frac{1}{E_q} \right) = \frac{2\pi^2 m^{3/2}}{\mu^{1/2}},
\]

\[
\int_q \left( E_q - \epsilon_q - \mu + \frac{\mu^2}{2E_q} \right) = \frac{m^{3/2} \mu^{5/2}}{15\pi^2},
\]

(A15)

we finally obtained

\[
V_0 = -\frac{m\mu^2}{8\pi a} \left( 1 - \frac{64}{15\pi^2} \sqrt{ma^2\mu} \right)
\]

(A16)

and in turn Eq. (17). Equations (A18) and (A19) are then deduced from \( \tilde{n} = -\partial V_0/\partial \mu \) and \( \kappa = \partial \tilde{n}/\partial \mu \).

Similarly, from Eq. (A11) and (A13), we deduce

\[
n_0 = \frac{m\mu}{4\pi a} - \frac{\mu}{2} \int_q \left( \frac{1}{\epsilon_q} - \frac{1}{E_q} \right) + \int_q \left( 1 - \frac{\epsilon_q + \mu}{E_q} \right)
\]

(A17)

to one-loop order (setting \( l = 1 \)), which leads to Eq. (20) using

\[
\int_q \left( 1 - \frac{\epsilon_q + \mu}{E_q} \right) = \frac{2}{3\pi^2} (m\mu)^{3/2}.
\]

(A18)

The superfluid density \( n_s \) is defined by the variation

\[
\delta \Gamma = \beta \frac{N_s}{2m} \int d^3r (\nabla \theta)^2
\]

(A19)

of the effective action when the superfluid order parameter \( \phi(r) = \sqrt{n_0 e^{i\theta(r)}} \) acquires a phase slowly varying in space. For a dilute Bose gas, Galilean invariance implies that \( n_s \) is equal to the fluid density, i.e., \( n_s(\mu, 0) = n(\mu, 0) \). To leading order, the sound mode velocity \( c = \sqrt{\beta_{1}/k} = \sqrt{\beta_{1}/k} \) is equal to \( \sqrt{\mu/m} \), in agreement with the small-\( q \) behavior of \( E_q = \sqrt{\epsilon_q (\epsilon_q + \mu)} \).

2. Finite temperature

Similarly, we can compute the pressure \( P(0, T) \) at vanishing chemical potential. For \( \mu = 0 \), the condensate density \( n_0 = 0 \) in the equilibrium state. The effective potential \( V_0 \) to one-loop order is then simply given by the noninteracting result

\[
V_0 = \frac{1}{\pi} \int_q \ln(1 - e^{-\beta E_q}) = -\zeta(5/2) \left( \frac{m}{2\pi} \right)^{3/2} T^{5/2},
\]

(A20)

where \( \zeta(x) \) is the Riemann zeta function.

3. Transition line

The one-loop approximation fails near the superfluid transition temperature \( T_c \). The transition temperature can nevertheless be determined from a perturbative approach in the normal state by considering the self-consistent one-loop self-energy correction (self-consistent Hartree-Fock approximation),

\[
\Sigma = -2g \sum_{\omega_n} \int_q \frac{e^{i\omega_n q - \xi_q - \Sigma}}{i\omega_n - \xi_q - \Sigma} = 2g \int_q n_B(\epsilon_q + \Sigma - \mu),
\]

(A21)

where \( n_B(x) = (e^{\beta x} - 1)^{-1} \) is the Bose-Einstein distribution function. The transition occurs when the renormalized chemical \( \mu - \Sigma \) vanishes,

\[
\mu = 2g \int_q n_B(\epsilon_q) = 2g \zeta(3/2) \left( \frac{mT_c}{2\pi} \right)^{3/2}.
\]

(A22)

To lowest order, \( g = 4\pi a/m \), which gives Eq. (25).

APPENDIX B: STRONG-COUPLING RPA

In the strong-coupling RPA [20–24], the effective action is given by Eq. (39). This implies that in the Mott-insulating phase, the single-particle propagator takes the form

\[
G(q, i\omega) = \frac{G_{\text{loc}}(i\omega)}{1 - t_q G_{\text{loc}}(i\omega)},
\]

(B1)

where

\[
G_{\text{loc}}(i\omega) = \frac{\tilde{n} + 1}{i\omega + \mu - U\tilde{n} - \frac{i\omega}{\tilde{n}} - \mu - U(\tilde{n} - 1)}
\]

(B2)

is the local propagator. \( \tilde{n} \) denotes the mean (integer) number of bosons per site. The instability of the Mott insulator is signaled by the appearance of a pole in the propagator, i.e., \( 1 - t_q G_{\text{loc}}(i\omega = 0) = 0 \), which reproduces the mean-field
Additional particle. Hopping of this particle between sites $r \rightarrow t$ can be understood as follows. Let us add a particle at
\begin{equation}
\delta G_{\text{loc}}(0) = \frac{G_{\text{loc}}(0)}{i\omega - \lambda_q}.
\end{equation}
for $q, \omega \rightarrow 0$, with
\begin{equation}
Z_{\text{qp}} = \frac{m}{m^*} = \left| \frac{G_{\text{loc}}(0)}{2d t G_{\text{loc}}(0)} \right|,
\end{equation}
where $G_{\text{loc}}(i\omega) = \delta_{t0}G_{\text{loc}}(i\omega)$. As in Sec. IV A, we have performed a particle-hole transformation when we consider the lower branch of the transition line [hence the absolute value in Eq. (B5)].

In the limit $t \rightarrow 0$, Eq. (B5) leads to Eq. (53), a result which can be understood as follows. Let us add a particle at site $r$ to a Mott insulator with $n$ particles per site. In the limit $t \rightarrow 0$, the only possible dynamics is due to the motion of the additional particle. Hopping of this particle between sites $r$ and $t'$ involves the matrix element
\begin{equation}
\langle \bar{n}, r | \otimes (\bar{n} + 1; r') | \otimes | \bar{n}; t' \rangle = i(t\bar{n} + 1)
\end{equation}
if we denote by $\otimes_{r_i} | n_i; r_i \rangle$ the state with $n_i$ particles at site $r_i$. The “particle” eigenstates are therefore plane-wave states
\begin{equation}
|q\rangle = \frac{1}{\sqrt{N}} \sum_r e^{iqr} | \bar{n} + 1; r \rangle \otimes | \bar{n}; r' \rangle
\end{equation}
with a dispersion law $\lambda_q = \lambda_0 - 2t(\bar{n} + 1) \sum_{i=1}^N \cos q_i$ [with $\lambda_0$ a constant which takes the value $2d t(\bar{n} + 1)$ at the quantum critical point], which leads to an effective mass $m^*/m = 1/(\bar{n} + 1)$. The single-particle propagator reads as
\begin{equation}
G(q, i\omega) = \frac{|\langle q| \tilde{\psi}(q)|0 \rangle|^2}{i\omega - \lambda_q},
\end{equation}
where $|0\rangle = \otimes_r |\bar{n}; r \rangle$ denotes the ground state of the Mott insulator without the additional particle (in the limit $t \rightarrow 0$). We deduce the quasiparticle weight
\begin{equation}
Z_{\text{qp}} = |\langle q| \tilde{\psi}(q)|0 \rangle|^2 = \bar{n} + 1.
\end{equation}
A similar reasoning for the motion of a hole leads to $Z_{\text{qp}} = m/m^* = \bar{n}$.

**APPENDIX C: WARD IDENTITY $Z_C = Z_{\mu}$**

To lowest order in $\delta \mu$, the effective action (47) at the QCP is modified by
\begin{equation}
\delta \Gamma(\varphi^*, \varphi) = -Z_{\mu} \delta \mu \int_0^\beta d\tau \int d^3r \varphi^* \varphi.
\end{equation}
This implies that the effective potential is given by
\begin{equation}
V(\mu, n) = V(\mu_c, n) - Z_{\mu} \delta \mu.
\end{equation}
The invariance of the action $S$ in the local (time-dependent) gauge transformation
\begin{equation}
\psi_r \rightarrow \psi_r e^{i\alpha}, \quad \varphi^*_r \rightarrow \varphi^*_r e^{-i\alpha}, \quad \mu \rightarrow \mu + i\alpha
\end{equation}
implies that $Z_C \equiv Z_{(\mu_c)}$ satisfies the Ward identity [6]
\begin{equation}
Z_C = \frac{\partial^2 V}{\partial \mu \partial n}|_{\mu_c, n=0},
\end{equation}
which gives
\begin{equation}
Z_C = Z_{\mu_c}.
\end{equation}
[28] The NPRG result depends on the approximation used to solve the flow equations. We quote here the best result: see Refs. [5,6] for a detailed discussion.

[29] This result bears some analogy with Fermi liquid theory where gauge invariance ensures that the coupling of the electromagnetic scalar and vector potentials to the elementary excitations (Landau’s quasiparticles) is not renormalized. The renormalization of the interaction vertex between electromagnetic field and electrons cancels out the quasiparticle weight so that thermodynamic response functions do not depend on the quasiparticle weight $Z_{\text{qp}}$. See, e.g., P. Nozières, Interacting Fermi Systems (Benjamin, New York, 1964).

[31] $A \textit{priori}$ nothing prevents the regular part $P_r + \bar{n} \delta \mu$ of the pressure to depend on temperature. The NPRG results show that, as for the dilute Bose gas, this is not the case.
